

## 14. Urlingford/Johnstown Source

### 14.1 Introduction

The objectives of this chapter are:

- To delineate source protection zones for the Urlingford/Johnstown Water Supply Scheme.
- To outline the principal hydrogeological characteristics of the Urlingford/Johnstown area.
- To assist Kilkenny County Council in protecting the water supply from contamination.

The protection zones are delineated to help prioritise certain areas around the source in terms of pollution risk to the source. This prioritisation is intended to provide a guide in the planning and regulation of development and human activities. The implications of these protection zones are further outlined in 'Groundwater Protection Schemes' (DELG/EPA/GSI, 1999).

### 14.2 Location and Site Description

Two springs 1.5 km east of Urlingford make up the public drinking water source for Urlingford and Johnstown. The location of the springs is shown on Map 8 and Map 4N. The springs are located in the townland of Borrismore; one in pasture land (2315NWW204), and the other by the side of the road (2315NWW124).

Spring 2315NWW124 lies just beside the R693 and the Borrismore Stream. It is enclosed in a concrete sump which is 5.5 m by 6.5 m, the top being set 1.6 m above the stream level, almost flush with the road. Reportedly, the stream inundates the spring during higher flows.

Spring 2315NWW204 reportedly lies some 370 m south of the R693 road, but is inaccessible to County Council staff and their representatives. It is unknown whether any protective structures have been built, but it may also be susceptible to inundation from surface drainage.

Discharge from both springs flows under gravity along pipes to a sump at the Borrismore pump-house, 1.7 km to the north-west. Here it is chlorinated and fluoridated before being pumped to a water tower further north in Warrenstown.

### 14.3 Summary of Source Details

	Spring 2315NWW124	Spring 2315NWW204

\* Estimated.

\*\* County Council records from 1998 to 2001

\*\*\*County Council staff have indicated that occasions when the springs overflow are rare, and that generally usage matches discharge.

## **14.4 Methodology**

### **14.4.1 Desk Study**

Bedrock geology information was compiled from original 1:10560 (six inch) field sheets and from the GSI bedrock report for the area (Archer *et. al*, 1996). Details of the current abstraction rate were obtained from Kilkenny County Council. Data on private groundwater wells in the area was taken from GSI archives. Chemistry data was obtained from EPA and County Council records. Water levels were from GSI records.

### **14.4.2 Site Visits and Field Work**

Site visits and fieldwork included walkover surveys undertaken by both the Groundwater (0.5 day) and Quaternary (1 day) sections of the GSI to further investigate the subsoil and bedrock geology, the hydrogeology and the vulnerability to contamination. Two water samples were taken by the GSI on 04/10/2000 and 26/04/2001, and were submitted for analysis at the EPA laboratories in Kilkenny in accordance with their sampling and transportation guidelines.

### **14.4.3 Assessment**

Analytical equations and hydrogeological mapping were utilised to delineate protection zones around the source.

## **14.5 Topography and Surface Hydrology**

The Urlingford/Johnstown source is located 1.5 km east of Urlingford and almost 3 km south of Johnstown (see Maps 4N and 8). The Borrismore Stream flows past both springs, 100 m west of 2315NWW204 and immediately west of 2315NWW124. This stream originates just 1.5 km to the east of the springs, and flows around in a loop to join the River Goul 4.5 km to the north-west. The Goul is part of the Erkina River sub-catchment of the Nore Basin.

The two springs and the stream occur in gently undulating land, varying in elevation from 140 m O.D. to 120 m O.D. The stream valley is wide and low, and the Stream meanders in broad loops, frequently overflowing its banks during the winter. This gently undulating terrain continues westwards for some distance into Tipperary, but ends just 3 km to the north-east of the springs, against the steep slopes of the Slieveardagh Hills. These hills form the northern boundary to the Borrismore Stream catchment.

The valley has very gentle variable slopes of about 0.02 (1 in 50) around the supply springs, steepening to 0.15 (1 in 6) in the hills to the north-east.

There is a streamflow gauge on the Borrismore Stream, installed by the GSI and monitored in the 1970's. Low flows at this station are particularly low, and it was dry in the summer of 1976. The maximum recorded winter flow was 0.52 m<sup>3</sup>/sec.

The drainage density in the immediate area of the springs is low. The other main river in the area is the Nuenna River, which rises 4.5 km to the south-east of the Urlingford springs.

Note that karst features occur 1 km to the east of the springs, but they lie on the far side of a surface watershed and on a different aquifer to the Urlingford springs. They are not thought to be relevant in the context of groundwater flow to the springs.

## **14.6 Geology and Aquifers**

### **14.6.1 Bedrock**

The main rock types below the Urlingford/Johnstown source are the Aghmacart and Durrow limestone Formations. The Ballyadams limestone Formation underlies the area to the east of the springs. These formations are described in more detail in Chapters 2 and 4 of Volume I and their distribution in the

vicinity of the Urlingford/Johnstown springs is shown on Map 8. The springs are located in the Durrow Formation.

The Aghmacart and the Durrow Formations both consist of shaley limestones and are both classified as **locally important aquifers** which are **moderately productive only in local zones (LI)**. Fracture flow is expected to be dominant. Flows are expected to be concentrated in fractured and weathered zones. Given common weathering patterns, most flow is thought to be relatively shallow; concentrating in the top 10 m to 30 m of the rock profile. More detail on flow characteristics and aquifer classification criteria can be found in Chapter 4 of Volume I.

The Ballyadams Formation consists of clean limestone which have been extensively karstified. Springs, swallow holes, a turlough and collapse features can all be found in the areas where this rock-type occurs, and the groundwater flow regime is expected to demonstrate karstic characteristics. The Ballyadams has been classified as a **regionally important karst aquifer (Rk<sup>d</sup>)** (see Chapter 4, Volume I).

All these formations have been affected by faulting. Faulting and associated fracturing are likely to be a focus for groundwater flow.

The springs occur towards the centre of an anticline (upward fold in the rock mass). In the immediate vicinity of the springs, the Durrow and Aghmacart Formations dip at about 14° south eastwards. This means that the regionally important karstic aquifer dips away from the springs and is unlikely to play a direct role in influencing groundwater flow to the springs.

#### 14.6.2 Subsoil

The main subsoil types in the area are gravel, alluvium, and glacial till. These materials are described in more detail in Chapter 3 of Volume I and their distribution in the vicinity of the Urlingford/Johnstown springs is shown on Map 2N.

Gravel deposits underlie the spring and are the most widespread subsoil in the area, and further east along the Nuenna River, they are classed as a **Locally important gravel (Lg)** aquifer (see Section 4.18.4 of Volume I). In the area around the Urlingford springs, however, they rarely exceed 5 m in thickness and are too thin to be regarded as an aquifer. The alluvial deposits occur in thin strips along the Borrismore Stream. Thin tills are mapped to the west of the springs, near Urlingford. There are no subsoil materials classified as aquifers in the Urlingford/Johnstown area and the main significance of the subsoil materials is in vulnerability and recharge assessments. These issues are described in Sections 14.7 and 14.8.

### 14.7 Groundwater Vulnerability

#### 14.7.1 Introduction

The concept of vulnerability is discussed in Chapter 4 of Volume I. In essence, however, groundwater vulnerability is dictated by the nature and thickness of the material overlying the main groundwater 'target'. As discussed in Section 14.6, the main groundwater resource occurs within fractured bedrock. Consequently, the target is taken from the top of the bedrock formations, and considerations of groundwater vulnerability concern the permeability of the whole subsoil profile and the depth to bedrock.

#### 14.7.2 Permeability

A generalised subdivision of Kilkenny into three broad permeability types (high, moderate and low) is provided in Chapter 5 of Volume I. The sands and gravels around the spring supplies are thought to be generally high permeability, and are regarded as part of the Nuenna River sand and gravel region (refer to Chapter 5, Volume I). The alluvium is regarded as generally moderate permeability, as is the till.

### 14.7.3 Depth-to-rock

The variation in depth to rock in the vicinity of the Urlingford/Johnstown springs is presented on Map 3N. The data on this map come from drilling records housed in the GSI databases and detailed field mapping carried out in the 1900's.

In summary, the subsoils in the immediate vicinity of the springs are thought to be thin or absent, rarely exceeding 3 m in thickness. Three individual outcrops are in evidence, along with one borehole record which indicates a depth to rock of 2 m. The Borrismore Stream is small, and the alluvial deposits are unlikely to exceed 1 m in thickness. To the east of the springs, the depth to rock is thought to gradually increase to 3 to 10 m. However, depths are variable, with rock outcrops in evidence, and at least one borehole record indicating a depth to rock of 14 m. These variations are located over the Ballyadams limestones, and are typical of karstic rock.

### 14.7.4 Summary

The vulnerability categories in the vicinity of the Urlingford/Johnstown supply springs are shown on Map 9. In areas where the subsoils are likely to be less than 3 m thick, a vulnerability rating of generally 'extreme' has been applied. In areas to the east, where the gravel deposits are believed to be greater than 3 m thick, their likely high permeability means that a vulnerability rating of generally 'high' has been assigned.

The permeability estimations are based on regional-scale evaluations. Depth to rock interpretations are based on the available data cited here. However, permeability and particularly depth to rock can vary over a very small scale. As such, the vulnerability mapping provided will not be able to anticipate all the natural variation that occurs in an area. The mapping is intended only as a guide to land use planning and hazard surveys, and is not a substitute for site investigation for specific developments. Classifications may change as a result of investigations such as trial hole assessments for on-site domestic wastewater treatment systems. The potential for discrepancies between large scale vulnerability mapping and site-specific data has been anticipated and addressed in the development of groundwater protection responses (site suitability guidelines) for specific hazards. More detail can be found in 'Groundwater Protection Schemes' (DELG/EPA/GSI, 1999).

## 14.8 Rainfall, Evaporation and Recharge

The term 'recharge' refers to the amount of water replenishing the groundwater flow system. Recharge is generally estimated on an annual basis, and is assumed to consist of an input (i.e. annual rainfall) less water losses (i.e. annual evapotranspiration and runoff). The estimation of recharge is critical in source protection delineation as it largely dictates the size of the zone of contribution.

In areas where point recharge from sinking streams, etc, is discounted, the main parameters involved in recharge rate estimation are annual rainfall, annual evapotranspiration, and annual runoff<sup>27</sup>:

- Annual rainfall: 880 mm (Met Eireann average annual (1961-90), average of rainfall measured at Urlingford and Johnstown).
- Annual actual evapotranspiration (A.E.) losses: 450 mm. This figure ('actual evapotranspiration') was calculated assuming 95% of the country-wide potential evapotranspiration data presented in the "Agroclimatic Atlas of Ireland" (Collins and Cummins, 1996). Local measurements of actual evapotranspiration are not available.
- Potential recharge: 430 mm/year, based on average annual rainfall less estimated evapotranspiration.
- Annual runoff losses: 20% of potential recharge (90 mm/year). This is a typical figure used by the GSI in areas where the till cover is thin, and where drainage densities are low.

---

<sup>27</sup> Estimations used in this report have generally been rounded off to two significant figures

These calculations are summarised below:

Average annual rainfall (R)	880 mm
Estimated A.E.	450 mm
Potential Recharge (R – A.E.)	430 mm
Runoff losses factor (RO)	20%
Estimated Actual Recharge (R-A.E.) x (1-R.O)	340 mm

## 14.9 Groundwater levels

Groundwater level monitoring was carried out by the GSI on 43 observation wells in the karstic Ballyadams aquifer to the east of the springs, from 1974 to 1976 (Cawley, 1990). The same level of research was not extended to the Durrow Formation, but water levels are available for four wells in the area. All these levels were obtained during late summer, from wells penetrating the Durrow Formation, and should reflect low groundwater levels. They indicate that the watertable in the aquifer is generally quite shallow, probably between 5 m and 10 m below ground level. The distribution of levels is presented on Map 8. The distribution suggests that there is a groundwater low in the vicinity of the supply springs, with a groundwater high following the slight topographic ridge that runs north-south along the geological contact between the Durrow 'LI' aquifer and the Ballyadams karstic aquifer. This, coupled with the fact that water levels appear to be quite shallow, suggests that the slight topographic ridge forms the eastern limit of the catchment area ('zone of contribution') of the springs and that the karstic aquifer has little influence on the flow regime at the springs. The Borrismore stream originates in the Loughans turlough on the karst aquifer and dries-up in the summer, while the Urlingford supply springs reportedly do not dry-up. This provides supporting information to suggest that the flow regime feeding the springs is not karstic.

## 14.10 Groundwater Flow Directions and Gradients

It is inferred from water level data (Section 14.9) that groundwater flow in the vicinity of the supply springs follows local topography. Two north-south trending low ridges occur 700 m to the east and west of the springs. Groundwater flow is expected to move from these ridges and towards the springs and to the Borrismore Stream. The stream is likely to act as a partial cut-off drain to flows from the west and most flow to the springs is expected to occur from the eastern ridge. Note that groundwater flows within the karstic limestones further east are expected to follow quite different patterns, but they are not expected to contribute a significant portion of the flow to the supply springs.

Assuming that shallow groundwater flow predominates in this shaley limestone aquifer, the groundwater gradients have been estimated from topographic data and limited water level data to range from 0.004 (1 in 250) to 0.02 (1 in 50).

## 14.11 Hydrochemistry and Water Quality

Data on recent trends in water quality at the Urlingford springs are summarised graphically in Figure 14.1, and the source data can be found in Appendix V.

The following key points have been identified from the data:

- Data from analysis of hardness in four samples indicate a 'very hard' (>350 mg/l CaCO<sub>3</sub>) calcium-bicarbonate hydrochemical signature.
- Of the parameters examined in the eight available raw groundwater analyses, faecal coliforms, potassium, the potassium:sodium ratio, and nitrate are all regularly in excess of GSI guide levels. This combination of parameters, found in springs located in an extreme vulnerability setting suggests that one or more farmyard point hazards are contributing to the contamination at the springs.

The regional hydrochemistry of the Durrow (LI) Aghmacart (LI) and Ballyadams (Rk) aquifer systems are discussed in Chapter 4 of Volume I.

### 14.12 Aquifer Parameters

The main aquifer parameters of significance are permeability and porosity. Together with groundwater gradients, these parameters are used to estimate the extent of the inner source protection area.

The data used in this section are mainly estimations based on our understanding of the likely flow-regime in the Durrow aquifer system. No pump test data were available in the immediate vicinity of the Urlingford springs, but pump test records for a well belonging to the Glanbia well-field in Ballyragget were used to assist in the assessment. Well 2317SWW455 is situated in the Durrow Formation, about 16 km north-east of the springs, and was tested by KTC consultancy (Cullen, 1990).

A constant discharge test in November 1989 at 320 m<sup>3</sup>/day for 54 hours gave a final drawdown of 8 m, and a specific capacity of 40 m<sup>3</sup>/day/m. Analysis of the data from this test using the Jacob method provided a transmissivity estimate of 15 m<sup>2</sup>/d.

Using a conservative aquifer thickness estimate of 10 m, a permeability of 1.5 m/day has been derived from the transmissivity estimate.

A porosity of 0.01 has been assumed for the Durrow 'LI' aquifer on the valley floor. This is at the lower end of the typical range used by the GSI for bedrock aquifers (0.025 to 0.01) and reflects the belief that fracturing is not particularly dense in this portion of the aquifer.

### 14.13 Conceptual Model

This section provides a qualitative overview of the geological framework, recharge, flow and discharge patterns across the aquifer contributing groundwater to the source. It represents a summary of the main inferences drawn in previous sections, and provides a foundation upon which the quantitative analyses required for delineating source protection areas can be drawn.

- The Urlingford springs lie in the shaley limestones of the Durrow Formation, which are classed as a **locally important aquifer (LI)**. Shaley limestones of the Aghmacart Formation (also LI) occur 400 m to the west and dip under the springs at a depth of approximately 100 m. Flow in all these aquifers will generally concentrate along faults and fractures and within the upper, weathered zones.
- Subsoils consist predominantly of gravels less than 5 m in thickness in most places. Some alluvium is mapped along the Borrismore Stream, while thin tills are mapped to the west of the area. The subsoils are not considered aquifers and groundwater vulnerability in the bedrock aquifers is expected to increase from generally 'high' to generally 'extreme' moving westwards towards the springs.
- Water level data suggest that groundwater within the aquifer feeding the springs is mostly unconfined and follows local topographic divides.
- Transmissivities are low and the water table appears to be quite shallow. Consequently, most recharge is expected to occur locally, and most occur at shallow depths and follow short flowpaths within the Durrow Formation limestones.
- Groundwater flow to the springs is expected to come from the slight topographic ridge that occurs 700 m to the east.
- Where the Borrismore Stream flows across the Durrow Formation, it is considered to be in hydraulic continuity with groundwater, and is likely to act as a partial cut-off drain to flow from the west. However, the stream is small and some groundwater flow may move under the stream from the west. Consequently, the western half of the topographic catchment is also considered a possible source of recharge.
- The Durrow limestone is overlain by a karstic aquifer to the north-east, but flow to the springs is not believed to be significantly influenced by karstic flows from this area.

- Due to the likely low permeability of the Durrow Formation, groundwater gradients are probably similar to topographic gradients, and are estimated to range from 0.004 (1 in 250) to 0.02 (1 in 50).

## 14.14 Delineation of Source Protection Areas

### 14.14.1 Introduction

This section delineates the areas around the Urlingford/Johnstown springs that are believed to contribute groundwater to the springs flows, and that therefore require protection. The areas are delineated on the basis of the conceptualisation of the groundwater flow pattern as described in Section 14.13.

Two source protection areas are delineated:

- ◆ Inner Protection Area (SI), designed to give protection from microbial pollution;
- ◆ Outer Protection Area (SO), encompassing the remainder of the zone of contribution (ZOC) of the source.

### 14.14.2 Outer Protection Area

The Outer Protection Area (SO) is bounded by the complete catchment area to the source, i.e. the zone of contribution (ZOC), and is defined as the area required to support an abstraction from long-term recharge. The ZOC is controlled primarily by (a) the groundwater flow direction and gradient, (b) the rock permeability and (c) the recharge in the area. The ZOC is delineated using both analytical modelling and the results of hydrogeological mapping and conceptualisation. Given the limited amount of calibration data available, a full groundwater numerical model was not undertaken.

In order to provide a reasonable, but conservative, estimate of the size of the ZOC, a high abstraction of 1455 m<sup>3</sup>/day (531,100 m<sup>3</sup>/year) was used. This represents the highest recorded combined discharge of 970 m<sup>3</sup>/day multiplied by an additional safety factor of 1.5. This conservative discharge figure was used because topography is not well defined in the area, and, as such, the delineation of the ZOC is subject to more uncertainty than in sources like Piltown or Graiguenamanagh.

The boundaries of the analytical model were taken from hydrogeological mapping and the conceptualisation outlined in Section 14.13, and were as follows:

- **Northern boundary:** 100 m down-gradient of spring 2315NWW124.
- **Eastern boundary:** Ridge of higher ground extending northwards from Belle Vue House.
- **Western boundary:** Ridge of higher ground extending northwards from Tincashel townland and into Borrisbeg townland.
- **Southern boundary:** Line joining the eastern and western boundaries at their closest point.

These boundaries delineate the physical limits within which the ZOC is likely to occur and are shown on Map 10.

The area defined by these boundaries described above is approximately 2.3 km<sup>2</sup>. Most flow to the springs is expected to originate from the portion of this area to the east of the Borrismore Stream. This portion comprises 1.2 km<sup>2</sup>. However, water balance estimations suggest that the actual ZOC of the springs needs to be approximately 1.6 km<sup>2</sup> to supply sufficient rainfall recharge to support the spring flows as follows:

*Recharge area required to sustain discharge* = Discharge ÷ average annual depth of recharge.

*Recharge area required to sustain discharge* = (1455 × 365) ÷ 0.34

*Recharge area required to sustain discharge* = 1.6 km<sup>2</sup>

This suggests that the portion to the west of the Borrismore stream is also required.

In summary, the physical limits defined above are considered appropriate to delineate the extent of the Outer Protection Area (ZOC).

#### 14.14.3 Inner Protection Area

The Inner Protection Area (SI) is the area defined by a 100 day time of travel (TOT) to the source from a point below the water table and it is delineated to protect against the effects of potentially contaminating activities which may have an immediate influence on water quality at the source, in particular from microbial contamination.

Estimations of the extent of this area cannot be made by hydrogeological mapping and conceptualisation methods alone. Analytical modelling was therefore used to estimate the extent of this zone upgradient of the springs.

Subject to certain assumptions and conditions, Darcy's Law can be used to approximate groundwater flow velocities, as follows:

$$\text{Velocity} = \text{groundwater gradient} \times \text{permeability} \div \text{porosity}$$

Using the estimates derived in Sections 14.12 and 14.10 for gradient, permeability, and porosity (0.02, 1.5 m/day, and 0.01 respectively), the equation gives a velocity of 3 m/day. This could be treated as a 'reasonable worst case estimate'. In other words, though some more rapid flow paths may occur, it is thought that most groundwater will move up to 300 m in 100 days. Accordingly, the boundary of the SI has been delineated 300 m upgradient of the springs (refer to Map 10).

#### 14.15 Groundwater Protection Zones

The groundwater protection zones are obtained by integrating the source protection areas and vulnerability categories – giving a possible total of 8 source protection zones (see the matrix in the table below). In practice, this is done by superimposing the vulnerability map on the source protection area map. Each zone is represented by a code, e.g. **SI/H**, which represents an **Inner Source Protection area** where the groundwater is **highly** vulnerable to contamination. All of the hydrogeological settings represented by the zones may not be present around any given source. Just three groundwater protection zones are present around the Urlingford/Johnstown source (see Map 10), as shown in the matrix below.

**Matrix of Source Protection Zones**

VULNERABILITY RATING	SOURCE PROTECTION	
	<i>Inner</i>	<i>Outer</i>
<i>Extreme (E)</i>	SI/E	<i>not present</i>
<i>High (H)</i>	SI/H	SO/H
<i>Moderate (M)</i>	<i>not present</i>	<i>not present</i>
<i>Low (L)</i>	<i>not present</i>	<i>not present</i>

The appropriate responses imposing restrictions on development are presented in the document 'Groundwater Protection Schemes' (DELG/EPA/GSI, 1999).

#### 14.16 Land Use and Potential Pollution Sources

Agriculture in the area comprises pasture and tillage.

No detailed hazard survey was carried out as part of this study, but, on the basis of the water quality and vulnerability assessments (see Section 14.11), the main hazards within the ZOC are considered to be farmyard point sources.

Other potential hazards include landspreading, domestic wastewater treatment systems, application of inorganic fertilisers and pesticides, inundation of contaminants from the stream, and possible spillages along the road passing the springs. Note also that the track leading past spring 2315NWW124 to the Borrismore Stream appears to be frequently used as a dumping ground. Toxic chemicals (e.g. fuel oil) dumped here could reach the spring.

The nitrate concentrations are consistently elevated and merit some additional consideration. Some broad, ‘back-of-the-envelope’ estimations of the number of domestic wastewater treatment systems required to produce the measured nitrogen loading in the springs are provided below:

- *Typical nitrogen concentration in spring flow: 9 mg/l N*
- *Typical ‘background’ nitrogen concentration<sup>28</sup>: 5.5 mg/l N*
- *Estimated additional contribution of nitrogen from human activities in the ZOC:  $9 - 5.5 = 3.5$  mg/l N*
- *Minimum estimated total spring flow: 644,000 l/day.*
- *Estimated minimum nitrogen loading in spring:  $644,000 \times 3.5 \div 1000,000 \approx 2.3$  kg/day N.*
- *Estimated ‘natural’ nitrogen loading in recharge waters<sup>29</sup>: 0.1 mg/l N @ 644,000 l/day  $\rightarrow$  0.06 kg/day N.*
- *Estimated additional loading from human activities in the ZOC =  $2.3 - 0.06 \approx 2.3$  kg/day N.*
- *Assuming all additional loading is derived from septic tanks, the population equivalent of the additional septic tank loading: 2.3 kg/day N @ 50 mg N/l/person @ 180 l effluent/person  $\approx$  250 people.*

In other words, it is estimated that the waste from at least 250 people living in the ZOC would be required to balance all the nitrogen loading observed in the spring waters. Note that the calculations have used the minimum estimated spring flow (644 m<sup>3</sup>/day) and have assumed that all the nitrogen from the septic tanks is converted to nitrate. In practice, some of the nitrogen will not become mobile in the subsurface, and average springflows are greater than 644 m<sup>3</sup>/day. As such, the population equivalent suggested by these ‘back-of-the-envelope’ estimations comprises a minimum number required to balance the observed nitrogen concentrations if septic effluent were the only influence on nitrate concentrations at the source. It is unlikely that this number of people live and use septic systems within the ZOC and, as such, the estimations provide evidence that other sources of nitrogen (such as farmyards) are contributing to the nitrate problem at the springs.

#### 14.17 Conclusions and Recommendations

- ◆ The two springs serving the Urlingford/Johnstown water supply scheme are both intermediate yielding springs, which are located in a locally important shaley limestone aquifer.
- ◆ The area around the supply is ‘highly’ to ‘extremely’ vulnerable to contamination and both springs are potentially vulnerable to inundation by the Borrismore stream.
- ◆ The protection zones delineated in this chapter are based on our current understanding of groundwater conditions and on the available data. Additional data obtained in the future may indicate that amendments to the boundaries are necessary.
- ◆ It is recommended that:
  - chemical and bacteriological analyses of raw water should be carried out monthly (refer to Section 7.9), in addition to analysis of treated samples. The chemical analyses should include all major ions - calcium, magnesium, sodium, potassium, ammonium, bicarbonate,

<sup>28</sup> Taken as the typical concentration in Clomantagh spring, which lies 6 km to the east in a similar hydrogeological and climatological environment.

<sup>29</sup> Loading estimates taken from EPA, 2000. The figures assume no denitrification and subsequent attenuation of nitrogen will occur in the subsurface.

sulphate, chloride, and nitrate. More occasional analyses of other parameters such as pesticides and hydrocarbons is also recommended;

- care should be taken in allowing any activities or developments which might significantly increase nitrate levels;
- the potential hazards in the ZOC should be located and assessed;
- dumping around the spring close to the road be discouraged as much as possible.

# **Appendix IV: Discussion of the Key Indicators of Domestic and Agricultural Contamination of Groundwater**

## Appendix IV: Discussion Of the Key Indicators of Domestic and Agricultural Contamination of Groundwater

### A.1 Introduction

This appendix is adapted from Daly, 1996.

There has been a tendency in analysing groundwater samples to test for a limited number of constituents. A "full" or "complete" analysis, which includes all the major anions and cations, is generally recommended for routine monitoring and for assessing pollution incidents. This enables (i) a check on the reliability of the analysis (by doing an ionic balance), (ii) a proper assessment of the water chemistry and quality and (iii) a possible indication of the source of contamination. A listing of recommended and optional parameters are given in Table A1. It is also important that the water samples taken for analysis have not been chlorinated - this is a difficulty in some local authority areas where water take-off points prior to chlorination have not been installed.

The following parameters are good contamination indicators: E.coli, nitrate, ammonia, potassium, chloride, iron, manganese and trace organics.

**TABLE A1**

<b>Recommended Parameters</b>		
Appearance	Calcium (Ca)	Nitrate (NO <sub>3</sub> )*
Sediment	Magnesium (Mg)	Ammonia (NH <sub>4</sub> and NH <sub>3</sub> )*
pH (lab)	Sodium (Na)	Iron (Fe)*
Electrical Conductivity (EC)*	Potassium (K)*	Manganese (Mn)*
Total Hardness	Chloride (Cl)*	
General coliform	Sulphate (SO <sub>4</sub> )*	
E. coli *	Alkalinity	
<b>Optional Parameters (depending on local circumstances or reasons for sampling)</b>		
Fluoride (F)	Fatty acids *	Zinc (Zn)
Orthophosphate	Trace organics *	Copper (Cu)
Nitrite (NO <sub>2</sub> )*	TOC *	Lead (Pb)
B.O.D.*	Boron (B) *	Other metals
Dissolved Oxygen *	Cadmium (Cd)	
<b>* good indicators of contamination</b>		

### A.2 Faecal Bacteria and Viruses

*E. coli* is the parameter tested as an indicator of the presence of faecal bacteria and perhaps viruses; constituents which pose a significant risk to human health. The most common health problem arising from the presence of faecal bacteria in groundwater is diarrhoea, but typhoid fever, infectious hepatitis and gastrointestinal infections can also occur. Although *E. coli* bacteria are an excellent indicator of pollution, they can come from different sources - septic tank effluent, farmyard waste, landfill sites, birds. The faecal coliform : faecal streptococci ratio has been suggested as a tentative

indicator to distinguish between animal and human waste sources (Henry *et al.*, 1987). However, researchers in Virginia Tech (Reneau, 1996) cautioned against the use of this technique.

Viruses are a particular cause for concern as they survive longer in groundwater than indicator bacteria (Gerba and Bitton, 1984).

The published data on elimination of bacteria and viruses in groundwater has been compiled by Pekdeger and Matthess (1983), who show that in different investigations 99.9% elimination of *E. coli* occurred after 10-15 days. The mean of the evaluated investigations was 25 days. They show that 99.9% elimination of various viruses occurred after 16-120 days, with a mean of 35 days for Polio-, Hepatitis, and Enteroviruses. According to Armon and Kott (1994), pathogenic bacteria can survive for more than ten days under adverse conditions and up to 100 days under favourable conditions; enteroviruses can survive from about 25 days up to 170 days in soils.

Bacteria can move considerable distances in the subsurface, given the right conditions. In a sand and gravel aquifer, coliform bacteria were isolated 100 ft from the source 35 hours after the sewage was introduced (as reported in Hagedorn *et al.*, 1981). They can travel several kilometres in karstic aquifers. In Ireland, research at Sligo RTC involved examining in detail the impact of septic tank systems at three locations with different site conditions (Henry, 1990; summarised in Daly, Thorn and Henry, 1993). Piezometers were installed down-gradient; the distances of the furthest piezometers were 8 m, 10 m and 9.5 m, respectively. Unsurprisingly, high faecal bacteria counts were obtained in the piezometers at the two sites with soakage pits, one with limestone bedrock at a shallow depth where the highest count (max. 14 000 cfu's per 1000 ml) and the second where sand/gravel over limestone was present (max 3 000 cfu's per 100 ml). At the third site, a percolation area was installed at 1.0 m b.g.l; the subsoils between the percolation pipes and the fractured bedrock consisted of 1.5 m sandy loam over 3.5 m of poorly sorted gravel; the water table was 3.5 b.g.l. (So this site would satisfy the water table and depth to rock requirements of S.R.6:1991, and most likely the percolation test requirement.) Yet, the maximum faecal coliform bacteria count was 300 cfus per 100 ml. Faecal streptococci were present in all three piezometers. It is highly likely that wells located 30 m down gradient of the drainage fields would be polluted by faecal bacteria.

As viruses are smaller than bacteria, they are not readily filtered out as effluent moves through the ground. The main means of attenuation is by adsorption on clay particles. Viruses can travel considerable distances underground, depths as great as 67 m and horizontal migrations as far as 400 m have been reported (as reported in US EPA, 1987). The possible presence of viruses in groundwater as a result of pollution by septic tank systems is a matter of concern because of their mobility and the fact that indicator bacteria such as faecal coliforms have been found not to correlate with the presence of viruses in groundwater samples (US EPA, 1987).

The natural environment, in particular the soils and subsoils, can be effective in removing bacteria and viruses by predation, filtration and absorption. There are two high risk situations: (i) where permeable sands and gravels with a shallow water table are present; and (ii) where fractured rock, particularly limestone, is present close to the ground surface. The presence of clayey gravels, tills, and peat will, in many instances, hinder the vertical migration of microbes, although preferential flow paths, such as cracks in clayey materials, can allow rapid movement and bypassing of the subsoil.

### **A.3 Nitrate**

Nitrate is one of the most common contaminants identified in groundwater and increasing concentrations have been recorded in many developed countries. The consumption of nitrate rich water by young children may give rise to a condition known as methaemoglobinaemia (blue baby syndrome). The formation of carcinogenic nitrosamines is also a possible health hazard and epidemiological studies have indicated a positive correlation between nitrate consumption in drinking

water and the incidence of gastric cancer. However, the correlation is not proven according to some experts (Wild and Cameron, 1980). The EC MAC for drinking water is 50mg/l.

The nitrate ion is not adsorbed on clay or organic matter. It is highly mobile and under wet conditions is easily leached out of the rooting zone and through soil and permeable subsoil. As the normal concentrations in uncontaminated groundwater is low (less than 5 mg/l), nitrate can be a good indicator of contamination by fertilisers and waste organic matter.

In the past there has been a tendency in Ireland to assume that the presence of high nitrates in well water indicated an impact by inorganic fertilisers. This assumption has frequently been wrong, as examination of other constituents in the water showed that organic wastes - usually farmyard waste, probably soiled water - were the source. The nitrate concentrations in wells with a low abstraction rate - domestic and farm wells - can readily be influenced by soiled water seeping underground in the vicinity of the farmyard or from the spraying of soiled water on adjoining land. Even septic tank effluent can raise the nitrate levels; if a septic tank system is in the zone of contribution of a well, a four-fold dilution of the nitrogen in the effluent is needed to bring the concentration of nitrate below the EU MAC (as the EU limit is 50 mg/l as NO<sub>3</sub> or 11.3 mg/l as N and assuming that the N concentration in septic tank effluent is 45 mg/l).

The recently produced draft county reports by the EPA on nitrate in groundwater show high levels of nitrate in a significant number of public and group scheme supplies, particularly in south and southern counties and in counties with intensive agriculture, such as Carlow and Louth. This suggests that diffuse sources – landspreading of fertilisers – is having an impact on groundwater.

In assessing regional groundwater quality and, in particular the nitrate levels in groundwater, it is important that:

- (i) conclusions should not be drawn using data only from private wells, which are frequently located near potential point pollution sources and from which only a small quantity of groundwater is abstracted;
- (ii) account should be taken of the complete chemistry of the sample and not just nitrate, as well as the presence of *E. coli.*;
- (iii) account should be taken of not only the land-use in the area but also the location of point pollution sources;
- (iv) account should be taken of the regional hydrogeology and the relationship of this to the well itself. For instance, shallow wells generally show higher nitrate concentrations than deeper wells, low permeability sediments can cause denitrification, knowledge on the groundwater flow direction is needed to assess the influence of land-use.

## **A.4 Ammonia**

Ammonia has a low mobility in soil and subsoil and its presence at concentrations greater than 0.1 mg/l in groundwater indicates a nearby waste source and/or vulnerable conditions. The EU MAC is 0.3 mg/l.

## **A.5 Potassium**

Potassium (K) is relatively immobile in soil and subsoil. Consequently the spreading of manure, slurry and inorganic fertilisers is unlikely to significantly increase the potassium concentrations in groundwater. In most areas in Ireland, the background potassium levels in groundwater are less than 3.0 mg/l. Higher concentrations are found occasionally where the rock contains potassium e.g. certain granites and sandstones. The background potassium:sodium ratio in most Irish groundwaters is less than 0.4 and often 0.3. The K:Na ratio of soiled water and other wastes derived from plant organic

matter is considerably greater than 0.4, whereas the ratio in septic tank effluent is less than 0.2. Consequently a K:Na ratio greater than 0.4 can be used to indicate contamination by plant organic matter - usually in farmyards, occasionally landfill sites (from the breakdown of paper). However, a K:Na ratio lower than 0.4 does not indicate that farmyard wastes are **not** the source of contamination (or that a septic tank is the cause), as K is less mobile than Na. (Phosphorus is increasingly a significant pollutant and cause of eutrophication in surface water. It is not a problem in groundwater as it usually is not mobile in soil and subsoil).

## **A.6 Chloride**

The principle source of chloride in uncontaminated groundwater is rainfall and so in any region, depending on the distance from the sea and evapotranspiration, chloride levels in groundwater will be fairly constant. Chloride, like nitrate, is a mobile anion. Also, it is a constituent of organic wastes. Consequently, levels appreciably above background levels (12-15 mg/l in Co. Offaly, for instance) have been taken to indicate contamination by organic wastes such as septic tank systems. While this is probably broadly correct, Sherwood (1991) has pointed out that chloride can also be derived from potassium fertilisers.

## **A.7 Iron and manganese**

Although they are present under natural conditions in groundwater in some areas, they can also be good indicators of contamination by organic wastes. Effluent from the wastes cause deoxygenation in the ground which results in dissolution of iron (Fe) and manganese (Mn) from the soil, subsoil and bedrock into groundwater. With reoxygenation in the well or water supply system the Fe and Mn precipitate. High Mn concentrations can be a good indicator of pollution by silage effluent. However, it can also be caused by other high BOD wastes such as milk, landfill leachate and perhaps soiled water and septic tank effluent.

**Box A1 Warning/trigger Levels for Certain Contaminants**

As human activities have had some impact on a high proportion of the groundwater in Ireland, there are few areas where the groundwater is in a pristine, completely natural condition. Consequently, most groundwater is contaminated to some degree although it is usually not polluted. In the view of the GSI, assessments of the degree of contamination of groundwater can be beneficial as an addition to examining whether the water is polluted or not. This type of assessment can indicate where appreciable impacts are occurring. It can act as a warning that either the situation could worsen and so needs regular monitoring and careful land-use planning, or that there may be periods when the source is polluted and poses a risk to human health and as a consequence needs regular monitoring. Consequently, thresholds for certain parameters can be used to help indicate situations where additional monitoring and/or source protection studies and/or hazard surveys may be appropriate to identify or prevent more significant water quality problems.

Parameter	Threshold mg/l	EU MAC mg/l
Nitrate	25	50
Potassium	4	12
Chloride	30 (except near sea)	250
Ammonia	0.15	0.3
K/Na ratio	0.3-0.4	
Faecal bacteria	0	0

**Box A2 Summary : Assessing a Problem Area**

Let us assume that you are examining an area with potential groundwater contamination problems and that you have taken samples in nearby wells. How can the analyses be assessed?

***E. coli present*** ⇒ organic waste source nearby (except in karst areas), usually either a septic tank system or farmyard.

***E. coli absent*** ⇒ either not polluted by organic waste or bacteria have not survived due to attenuation or time of travel to well greater than 100 days.

***Nitrate > 25 mg/l*** ⇒ either inorganic fertiliser or organic waste source; check other parameters.

***Ammonia > 0.15 mg/l*** ⇒ source is nearby organic waste; fertiliser is not an issue.

***Potassium (K) > 5.0 mg/l*** ⇒ source is probably organic waste.

***K/Na ratio > 0.4 (0.3, in many areas)*** ⇒ Farmyard waste rather than septic tank effluent is the source. If < 0.3, no conclusion is possible.

***Chloride > 30 mg/l*** ⇒ organic waste source. However this does not apply in the vicinity of the coast (within 20 km at least).

In conclusion, faecal bacteria, nitrate, ammonia, high K/Na ratio and chloride indicate contamination by organic waste. However, only the high K/Na helps distinguish between septic tank effluent and farmyard wastes. So in many instances, while the analyses can show potential problems, other information is needed to complete the assessment.

Belview	02/10/1996	11:10:00						Calcium Hardness = 152 mg/l CaCO3	Very high nitrate.	
Belview	03/10/1996	10:30:00						Calcium Hardness = 144 mg/l CaCO3		
Bellview Water Supply	08/10/1996	10:30:00						Calcium Hardness = 144 mg/l CaCO3	Interference from background colonies on Total Coliform plate.	Very high Nitrate.
Spring at Paulstown Castle	09/01/1997	12:17:00						See GC/MS Purge & Trap analyses on separate sheet.		
Thomastown	10/01/1997	10:17:00								
Borehole No.9, Thomastown	10/01/1997	10:05:00						See GC/MS Purge & Trap analyses on separate sheet.	Octamethylcyclotetrasiloxane < 0.2 ug/l.	
Borehole at Dunmore	13/01/1997							Sample for GC/MS Purge & Trap analyses only. Results on separate sheet.	Octamethylcyclotetrasiloxane 0.7 ug/l.	
Spring at Paulstown Castle	17/02/1997	11:30:00						Octamethylcyclotetrasiloxane = 0.3 ug/l.		
Springs at Bausheenmore	17/02/1997	12:30:00						Octamethylcyclotetrasiloxane = 1.7 ug/l.	K/Na Ratio = 0.41	
Spring at Westcourt	17/02/1997	14:05:00						Octamethylcyclotetrasiloxane = 1.4 ug/l.		
Dunmore	09/05/1997							Very high ammonia.	Sample taken after land-fill leachate escaped to groundwater.	Approximate ammonia concentration.
Dunmore	09/05/1997							Strong odour and high ammonia.	Sample taken after land-fill leachate escaped to groundwater.	Approximate ammonia concentration.
Dunmore	09/05/1997							Odour of sulphide.	Sample taken after land-fill leachate escaped to groundwater.	Approximate ammonia concentration.
Dunmore	09/05/1997							Very high TOC, ammonia and nitrite results < serious contamination.	Sample taken after land-fill leachate escaped to groundwater.	Approximate ammonia concentration.
Dunmore	09/05/1997							Very high ammonia and high nitrite.	Sample taken after land-fill leachate escaped to groundwater.	Approximate ammonia concentration.
Dunmore	12/05/1997	10:45:00						Ammonia >1.5 mg/l as N.	Sample taken after leachate at landfill site escaped to groundwater	Amended report, ammonia is >1.5 and not <1.5 as reported on 15/5/97.
Dunmore	12/05/1997	10:55:00							Sample taken after leachate at landfill site escaped to groundwater	
Dunmore	12/05/1997	11:05:00							Sample taken after leachate at landfill site escaped to groundwater	No coliforms detected but possible interference from suspended solids.
Dunmore	12/05/1997	11:15:00							Sample taken after leachate at landfill site escaped to groundwater	
Dunmore	12/05/1997	11:25:00							Sample taken after leachate at landfill site escaped to groundwater	
Dunmore	12/05/1997	12:00:00							Sample taken after leachate at landfill site escaped to groundwater	Interference from suspended solids on the total coliform test.
Dunmore	12/05/1997	12:15:00							Sample taken after leachate at landfill site escaped to groundwater	Background interference on the total coliform test.
Dunmore	12/05/1997	12:30:00							Sample taken after leachate at landfill site escaped to groundwater	Very high coliform levels (total and faecal).
Dunmore	12/05/1997	15:30:00						High ammonia and nitrite concentrations.	Sample taken after leachate at landfill site escaped to groundwater	
Dunmore	12/05/1997	15:45:00						Very turbid. High ammonia indicative of pollution.	Sample taken after leachate at landfill site escaped to groundwater	Interference from suspended solids on the coliform tests (total & faecal).
Dunmore	12/05/1997	15:55:00						Very turbid. High nitrite. Odour detected.	Sample taken after leachate at landfill site escaped to groundwater	Background interference on the total coliform test.
Dunmore	12/05/1997	14:35:00						Turbidity > 100 NTU and ammonia > 110 mg/l N. Very high coliform levels.	Sample taken after leachate at landfill site escaped to groundwater	
Dunmore	12/05/1997	14:50:00						High ammonia and nitrite levels.	Sample taken after leachate at landfill site escaped to groundwater	Interference on the total coliform test.
Dunmore	12/05/1997	15:10:00							Sample taken after leachate at landfill site escaped to groundwater	Interference on the total coliform test.
